Cardiac natriuretic peptides for diagnosis of covert atrial fibrillation after acute ischaemic stroke: a meta-analysis of diagnostic accuracy studies

Kejia Zhang,1 Joseph Kamtchum-Tatuene 2, Mingxi Li,3 Glen C. Jickling1

ABSTRACT

Background and purpose Detection of atrial fibrillation (AF) after acute ischaemic stroke is pivotal for the timely initiation of anticoagulation to prevent recurrence. Besides heart rhythm monitoring, various blood biomarkers have been suggested as complimentary diagnostic tools for AF. We aimed to summarise data on the performance of cardiac natriuretic peptides for the diagnosis of covert AF after acute ischaemic stroke and to assess their potential clinical utility.

Methods We searched PubMed and Embase for prospective studies reporting the performance of B-type natriuretic peptide (BNP) or N-terminal pro-BNP (NT-proBNP) for the diagnosis of covert AF after acute ischaemic stroke. Summary diagnostic performance measures were pooled using bivariate meta-analysis with a random-effect model.

Results We included six studies focusing on BNP (n=1930) and three studies focusing on NT-proBNP (n=623). BNP had a sensitivity of 0.83 (95% CI 0.64 to 0.93), a specificity of 0.74 (0.67 to 0.81), a positive likelihood ratio of 3.2 (2.6 to 4.0) and a negative likelihood ratio of 0.23 (0.11 to 0.49). NT-proBNP had a sensitivity of 0.91 (0.65 to 0.98), a specificity of 0.77 (0.52 to 0.91), a positive likelihood ratio of 3.9 (1.8 to 8.7) and a negative likelihood ratio of 0.12 (0.03 to 0.48). Considering a pretest probability of 20%, BNP and NT-proBNP had post-test probabilities of 45% and 50%.

Conclusions NT-proBNP has a better performance than BNP for the diagnosis of covert AF after acute ischaemic stroke. Both biomarkers have low post-test probabilities and may not be used as a stand-alone decision-making tool for the diagnosis of covert AF in patients with acute ischaemic stroke. However, they may be useful for a screening strategy aiming to select patients for long-term monitoring of the heart rhythm.

INTRODUCTION

Atrial fibrillation (AF) is responsible for approximately 20% of all ischaemic strokes.1 Stroke secondary to AF is usually more severe and associated with greater recurrence and mortality rates.2 Oral anticoagulation is a readily available secondary prevention strategy. Therefore, timely and accurate diagnosis of AF after stroke is pivotal. The sensitivity of standard ECG for the detection of AF is low especially in patients with paroxysmal AF.3 Prolonged ECG monitoring has higher detection rates but is expensive, time consuming and hard to generalise to a routine clinical scenario.

Inflammation and haemodynamic stress are important pathophysiological substrates for AF and thrombus development in the left atrial appendage, and both factors trigger the production of natriuretic peptides by cardiomyocytes.4 The haemodynamic stress could result from underlying cardiac or systemic comorbidities but could also be a consequence of the catecholamine release after an acute stroke.5 6 Cardioembolic strokes usually cause larger brain lesions and are typically associated with higher levels of cardiac natriuretic peptides.7 9 Several studies have suggested that cardiac natriuretic peptides could serve as a useful biomarker for the diagnosis of AF in patients with ischaemic stroke.10 Previous meta-analyses have focused on the validity of cardiac natriuretic peptides for the diagnosis of cardioembolic stroke with documented paroxysmal or persistent AF or with evidence of other embolicigenic heart diseases.11 12 However, a diagnostic biomarker is more relevant in patients with stroke in whom there is no pre-existing evidence of AF. We conducted this systematic review and meta-analysis to summarise data on the performance of cardiac natriuretic peptides for the diagnosis of covert AF after acute ischaemic stroke and to assess their potential clinical utility.

METHODS

We searched PubMed and Embase, up to 15 December 2019, for prospective studies reporting the performance of cardiac natriuretic peptides for the diagnosis of covert AF after acute ischaemic stroke. Small cases series (<30 participants) and studies including patients with pre-existing or chronic AF were excluded. The search strategy is available

Agreement between reviewers for study selection was assessed using the Cohen’s kappa statistic which indicates the proportion of the possible beyond chance agreement that is attributable to the individual performance of the observers. Disagreements were solved through discussion and consensus. The Quality Assessment of Diagnostic Accuracy Studies-2 tool was used to assess the methodological quality of each study. A bivariate meta-analysis with random-effects model was performed to calculate the pooled sensitivity, specificity, positive likelihood ratio (PLR), negative likelihood ratio (NLR) and diagnostic OR (DOR) for B-type natriuretic peptide (BNP) and N-terminal pro-BNP (NT-proBNP). A hierarchical summary receiver operating characteristic
The performances of BNP and NT-proBNP for the
diagnosis of covert AF were analysed separately owing
to substantial differences in primary structures, plasma
levels, plasma half-lives, elimination pathways and anti-
bodies used in detection assays. Although AF was not
detected at the time of stroke onset or blood sampling in
the included studies, the analyses of diagnostic accuracy
were performed under the assumption that patients diag-
nosed with AF during follow-up already had an under-
lying paroxysmal AF that could be the cause of the stroke.

We investigated the interstudy heterogeneity by
assessing the presence of a threshold effect. This was done
by calculating the Spearman rank correlation coefficient
between true positive and false positive rates, computing
the I² index, and performing the χ² test on the Cochrane’s
Q statistic. Publication bias was assessed by Deeks’
funnel plot asymmetry test.

The clinical utility of the biomarkers was assessed
by computing post-test probabilities on Fagan nomo-
grams based on Bayes Theorem. We considered a
pretest probability of 20% since it is the proportion of
stroke attributed to AF and the proportion of patients
without carotid disease who were diagnosed with AF after
an average follow-up of 3.4 years in the New Approach
Rivaroxaban Inhibition of factor Xa in the Global Trial vs
Aspirin to Prevent Embolism in Embolic Stroke of Unde-
termined Source (NAVIGATE-ESUS) trial. We opted
to use the most recent estimate from the NAVIGATE-
ESUS trial rather than the 12.4% estimate from the
Cryptogenic Stroke and Underlying AF (CRYSTAL-AF)
trial because recent evidence suggests that patients with
embolic stroke of undetermined source who have an ipsi-
lateral mild carotid stenosis are less likely to have AF and
may have a large-vessel stroke. In the CRYSTAL-AF trial,
the lower incidence of AF despite the use of implantable
cardiac monitors may be due to the inclusion of patients
with mild carotid stenosis and the shorter duration of
follow-up.

All statistical tests were two-sided and statistical signifi-
cance defined as p≤0.05. Data analysis was performed with
the software STATA (V.13.0, StataCorp, College Station,
Texas, USA) using the dedicated MIDAS module. This
report is compliant with the Preferred Reporting Items
for Systematic Review and Meta-analysis of Diagnostic Test
Accuracy Studies guidelines. The database is available
from the corresponding author on reasonable request.

RESULTS
There were six studies of the diagnostic validity of BNP
(n=1930) and three for NT-proBNP (n=623) (online supple-
mental figure I). There was 97.8% agreement between the investigators for study inclusion (κ=0.86).

Five studies recruited patients within 24 hours of stroke
onset. In all studies, blood samples were collected on
admission. All patients had a 12-lead ECG and a 24 hours Holter ECG at baseline, followed by single or repeated prolonged monitoring periods. Levels of cardiac natriuretic peptides were measured using electrochemiluminescence immunosorbent assay in five studies and chemiluminescence immunosorbent assay in four. The mean age of the participants was >60 years in eight studies and the mean time to AF diagnosis ranged from 3 to 36 days. The characteristics of the included studies are summarised in online supplemental table II. The overall quality of the included studies was high (online supplemental figures II and III).

The summary performance measures for the diagnosis of covert AF using BNP were as follows: sensitivity of 0.83 (95% CI 0.64 to 0.93), specificity of 0.74 (95% CI 0.67 to 0.81), PLR of 3.2 (95% CI 2.6 to 4.0), NLR of 0.23 (95% CI 0.11 to 0.49), DOR of 14 (95% CI 7 to 27) and AUC of 0.82 (95% CI 0.79 to 0.85) (figure 1 and online supplemental figure IV). Using a pretest probability of 20%, the post-test probability of AF was 45% for a positive test and 5% for a negative test (figure 2). There was a positive correlation between true and false positive rates (Spearman ρ=0.54), suggesting a threshold effect responsible for 64% of the observed heterogeneity (I²=97%, p<0.001). The Deeks’ Funnel plot asymmetry test was not significant, suggesting no publication bias (p=0.55, online supplemental figure V).

The summary performance measures for the diagnosis of covert AF using NT-proBNP were as follows: sensitivity of 0.91 (95% CI 0.65 to 0.98), specificity of 0.77 (95% CI 0.52 to 0.91), PLR of 3.9 (95% CI 1.8 to 8.7), NLR of 0.12 (95% CI 0.03 to 0.48), DOR of 34 (95% CI 8 to 138) and AUC of 0.91 (95% CI 0.88 to 0.93) (figure 1 and online supplemental figure IV). Using a pretest probability of 20%, the post-test probability of AF is 50% for a positive test and 3% for a negative test (figure 2). There was positive correlation between true and false positive rates (Spearman ρ=0.40), suggesting a threshold effect responsible for 47% of the observed heterogeneity (I²=90%, p<0.001). The Deeks’ Funnel plot asymmetry test was not significant, suggesting no publication bias (p=0.17, online supplemental figure V).

DISCUSSION

NT-proBNP had a significantly higher AUC than BNP. NT-proBNP also had higher summary estimates of sensitivity, specificity, PLR and DOR although there was a wide overlap of CIs which may be explained by the small number of studies available for this meta-analysis. These results suggest that NT-proBNP has a better performance than BNP for the diagnosis of covert AF after acute ischaemic stroke. Our findings are consistent with the results of a recent individual patient data meta-analysis showing that the multivariable model including NT-proBNP had higher predictive value for cardioembolic stroke than the model including BNP in patients with stroke of undetermined cause at baseline. The better performance of NT-proBNP could be explained by the fact that it has a longer half-life than BNP (120 vs 20 min), thus increasing the chances of detecting a rise in plasma levels after a transient episode of AF.

Despite their high sensitivity, the clinical utility indicators of BNP and NT-proBNP remain suboptimal. It is considered that a PLR >10 and a NLR <0.1 provide strong evidence of the capacity of a test to rule in or rule out a diagnosis in most circumstances. Both biomarkers do not meet these requirements. Only about 50% of patients testing positive for BNP or NT-proBNP are likely to have AF if the pretest probability is 20%, no matter the cut-off used. Therefore, cardiac natriuretic peptides may not be used as a stand-alone decision-making tool for the diagnosis of covert AF in patients with acute ischaemic stroke. However, they may be useful for a screening strategy aiming to select patients for long-term monitoring of the heart rhythm. They could also be used to select high-risk patients prior to randomisation into anticoagulation trials as currently done in the atrial cardio- and antithrombotic drugs in prevention after cryptogenic stroke trial (NCT03192215). Further studies are needed to investigate if the performance of cardiac natriuretic peptides could be improved by the combination with transcriptomic biomarkers.

Due to the limited number of included studies, subgroup and metaregression analyses could not be performed to explore how the diagnostic performance of BNP and NT-proBNP is influenced by patients’ clinical characteristics, notably age, presence of cardiovascular risk factors and cardiac comorbidities (heart failure, coronary atherosclerosis, valvular diseases), presence of kidney failure and use of diuretics, method of cardiac monitoring and time to diagnosis of AF, time from stroke onset to blood collection, size of brain infarction, treatment with beta-blockers and systemic inflammation. Analysis of data from ongoing trials and future observational studies may clarify if cardiac natriuretic peptides have a better clinical utility profile in specific subgroups of patients with acute ischaemic stroke.
